

1 Patent # \_\_\_\_\_

2 **TITLE** Particle Accelerator Space Engine

3 John P. Foster, St. Augustine, Florida, 32095

4 Filed \_\_\_\_\_ Serial No. \_\_\_\_\_

5 2 claims

6 **Cross Reference to Related Applications** - This invention pertains to a propulsion device  
7 employing particle accelerator accelerator / storage ring / braking device technology to provide  
8 novel method and mechanism for vertical propulsion, referred to as "Gyroscopic Lift". The  
9 invention also utilizes particle accelerator / storage ring / braking device in secondary method  
10 for horizontal propulsion relative to the ship, referred to as "Impulse Propulsion".

11 **Federal Status of Funding** - The invention described herein is not a Federally funded research  
12 and development project.

13 **Background of Invention** - The invention utilizes principle operations of three types of  
14 particle stream technology in a new and novel application. Those technologies are particle  
15 accelerators, storage rings, and braking devices. The particle accelerator / storage ring / braking  
16 device shall heretofor be referred to as Particle Accelerator Space Engine. Particle accelerators  
17 have been designed for bombardment of particles such as to start a nuclear chain reaction, or  
18 create new man made elements, or study anti-matter. Storage rings have been designed for the  
19 purpose of circulating matter at a fixed high velocity so as to store kinetic energy associated  
20 with moving particles. Braking devices employ reverse technology of particle accelerators, to  
21 enable particles in a particle stream to be slowed down.

22 **Brief Summary of the Invention** - This invention seeks to utilize particle accelerator/  
23 storage ring/ braking device technology in a new and novel applications concerning methods of

24 propulsion. The Particle Accelerator Space Engine is mobile, allowing particle motion to cause  
25 reactive motion to the engine, and vice versa. Mathematical trajectories presented here depict  
26 how particle motion drives the engine through space.

27 **Brief description of drawings -** Figures 1 through 9 are designed to show the  
28 methodology and mathematics for vertical propulsion, referred to as a new principle of  
29 aerospace physics called “Gyroscopic Lift”. Figure 1 represents a typical placement for two  
30 counter-circulatory particle accelerator doughnuts. Figure 2 represents circulatory path for  
31 particles found in one of the doughnuts of the Particle Accelerator Space Engine, and a  
32 directional analysis of velocity vectors for 4 theoretic point particles as related to the earth.  
33 Figure 3 represents a directional analysis of radial acceleration relative to the earth for a typical  
34 point particle at an instantaneous moment in time. Figure 4 represents a particle trajectory for  
35 an individual particle as the particle moves through time and space. Figure 5 represents a  
36 directional analysis of radial acceleration as a cumulative effect for the sum of all theoretic  
37 point particles in the circulatory path. Figure 6 is a pair of two dimensional graphs depicting all  
38 of the accelerative influences exerted upon point particles on two respective geometric planes.  
39 Figure 7 is a mathematical formula for determining acceleration, and thrust related to vertical  
40 propulsion. Figure 8 is an example of the formula for thrust found in figure 7. Figure 9 is a  
41 mathematic theoretic example for determining a ship's vertical acceleration rate. Figures 10  
42 through 12 are a series depicting the methodology and mathematics for a horizontal propulsion,  
43 referred to as a new principle of aerospace physics called “Impulse Propulsion”. Figure 10 is a  
44 depiction of centripetal acceleration in radial coordinates for alternating accelerative/  
45 decelerative  $\frac{1}{2}$  cycles. Figure 11 is a depiction for change in centripetal acceleration in Cartesian

46 coordinates for alternating accelerative/ decelerative  $\frac{1}{2}$  cycles. Figure 12 is a particle trajectory  
47 for an individual particle as it moves through time and space.

48 **Detailed description -** Referring now to the drawings; particle accelerator Space  
49 Engine is composed of two circular particle accelerator/ storage ring/ braking devices , mounted  
50 one above the other, with particle streams traveling in counter-rotational directions, as depicted  
51 in figure 1. Each of these devices may produce horizontal and / or vertical propulsion. The  
52 configuration is for the purpose of stabilizing cabin motion, and complimenting counter-  
53 rotational particle motions. Both clockwise, and counterclockwise particle accelerators produce  
54 upward thrust, but are capable of providing each other with equal but opposite recoil  
55 acceleration, to prevent the cabin from rotating. The determination of function at a given time as  
56 a particle accelerator, storage ring, or braking device is regulated by particle stream velocity at  
57 a given time. The ability to kick a particle to a higher, stable, or lower velocity is regulated by  
58 timing and intensity of particle accelerator station kicks, and magnetic forces located about the  
59 circumference of the doughnuts. Although these technologies are common practice to the field  
60 of particle accelerators, they are not always categorized as such. Mention is made to include the  
61 fields of storage rings and braking devices. Figure 2 is a representation of one of the circular  
62 particle accelerators with particles traveling counterclockwise. Particles are circulated in the  
63 device at velocities above circular orbit velocity for relative altitude of the planet. For  
64 mathematical purposes, symmetry can be used to treat the mass of the particle stream as if it  
65 were equally distributed to points that intersect the xz and yz planes, at an instantaneous  
66 moment in time. These theoretic point particles are labeled H, I, J and K. Figure 2 also depicts  
67 the directional component of velocity for each point particle perpendicular to gravity. Figure 3  
68 is a typical representation depicting how the instantaneous component of velocity for a point

69 particle interacts with the earth's gravity to provide radial acceleration relative to the planet.

70 Mathematically, radial acceleration is computed as  $v^2/r$ , with  $r$  representing the radius to the

71 planet center. In all scientific examples, objects that travel perpendicular to gravity above

72 circular orbit velocity continue on, to gain altitude as time progresses. In such state, the particle

73 may be regarded as sidestepping gravity, at a faster rate than falling. Typically, an object that

74 has velocity perpendicular to gravity between circular orbit velocity and escape velocity enters

75 the ascending side of an elliptic orbit.; At escape velocity, an object enters the ascending side

76 of a parabolic obit, and above escape velocity an object enters the ascending side of a

77 hyperbolic orbit. Unless other perturbing forces are present, to throw the object off track, it

78 always gains altitude. In the Particle Accelerator Space Engine, the magnitude of velocity for

79 the particle stream is much greater than escape velocity. The effect of an ascending hyperbolic

80 orbit with a centripetal perterbation towards the center axis of the Particle Accelerator Space

81 Engine creates an ascending helical trajectory. Figure 4 is a depiction of an ascending helical

82 trajectory for an individual point particle as it moves through 3 dimensional space. The upward

83 spiraling trajectory of the point particle is contained by electromagnetic forces within the

84 Particle Accelerator Space Engine, but the forces exerted by the particle stream, onto the

85 engine, create lift for the entire device and aerospace craft. Figure 5 is a 3 dimensional depiction

86 of all the theoretic point particles, and the instantaneous acceleration vectors of gravity,

87 centripetal acceleration relative to the center of the accelerator, and radial acceleration relative

88 to the planet. Figure 6 is a pair of two dimensional graphs representing the xz plane and yz

89 planes. All of the acceleration vectors depicted in figure 5 are tranccribed to figure 6, such that

90 trigonometric relations can be easily seen. The trigonomic triangles enable the vectors to be

91 broken down to component vectors for their respective axis. Point particle H is traveling

- 92 perpendicular to the page outward. Point particle J is traveling perpendicular to the page inward.
- 93 Point particle K is traveling perpendicular to the page outward. Point particle I is traveling
- 94 perpendicular to the page inward. Sample of initialing:
- 95  $a_{(rxH)}$  = radial acceleration component, to earth center relative to x axis for particle H.
- 96  $a_{(rzH)}$  = radial acceleration component, to earth center relative to z axis for particle H.
- 97  $a_{(cxH)}$  = centripetal acceleration component, to ring center relative to x axis for particle H.
- 98  $a_{(czH)}$  = centripetal acceleration component, to ring center relative to z axis for particle H
- 99  $a_{(gxH)}$  = gravity acceleration component, to earth center relative to x axis for particle H.
- 100  $a_{(gzH)}$  = gravity acceleration component, to earth center relative to z axis for particle H.
- 101  $a_{(rxJ)}$  = radial acceleration component, to earth center relative to x axis for particle J.
- 102  $a_{(rzJ)}$  = radial acceleration component, to earth center relative to z axis for particle J.
- 103  $a_{(cxJ)}$  = centripetal acceleration component, to ring center relative to x axis for particle J.
- 104  $a_{(czJ)}$  = centripetal acceleration component, to ring center relative to z axis for particle J
- 105  $a_{(gxJ)}$  = gravity acceleration component, to earth center relative to x axis for particle J.
- 106  $a_{(gzJ)}$  = gravity acceleration component, to earth center relative to z axis for particle J.
- 107  $a_{(ryK)}$  = radial acceleration component, to earth center relative to y axis for particle K.
- 108  $a_{(rzK)}$  = radial acceleration component, to earth center relative to z axis for particle K.
- 109  $a_{(cyK)}$  = centripetal acceleration component, to ring center relative to y axis for particle K.
- 110  $a_{(czK)}$  = centripetal acceleration component, to ring center relative to z axis for particle K
- 111  $a_{(gyK)}$  = gravity acceleration component, to earth center relative to y axis for particle K.
- 112  $a_{(gzK)}$  = gravity acceleration component, to earth center relative to z axis for particle K.
- 113  $a_{(ryI)}$  = radial acceleration component, to earth center relative to y axis for particle I.
- 114  $a_{(rzI)}$  = radial acceleration component, to earth center relative to z axis for particle I.

115  $a_{(cyl)}$  = centripetal acceleration component, to ring center relative to y axis for particle I.

116  $a_{(czl)}$  = centripetal acceleration component, to ring center relative to z axis for particle I

117  $a_{(gyI)}$  = gravity acceleration component, to earth center relative to y axis for particle I.

118  $a_{(gzI)}$  = gravity acceleration component, to earth center relative to z axis for particle I.

119         Figure 7 is a mathematical formula for determining gyroscopic lift. It sums the  
120 component vectors of acceleration in a manner that reveals an equation for instantaneous thrust,  
121 and instantaneous acceleration in the z direction. To describe the mathematical process: An  
122 initial equation is generated for Force exerted by each of the 4 theoretic point particles. Each  
123 particle is assigned  $\frac{1}{4}$  of the mass of the particle stream which is multiplied by the cumulative  
124 accelerations exerted on or by the particle. The four point particle equations are written one  
125 above another so as to form columns for summation. Although the hypotenuse' for the 4  
126 theoretic point particles may differ in direction, their magnitudes are equal, and their component  
127 vectors either compliment one another or oppose one another. When all of the acceleration  
128 vectors are broken down into vector components then summed, the result causes many vector  
129 components to cancel each other out, leaving only acceleration in the z direction, referred to as  
130  $a_{(z)}$ . The mathematical formula for vertical acceleration is :  $a_{(z)} \approx v^2/r + a_g$  . The mathematical  
131 formula for vertical thrust is :  $m_{\text{particle stream}} a_{(z)} = \text{thrust}$ .

132         Figure 8 is a mathematical model presented for the purpose of demonstrating use of the  
133 equations for vertical thrust. In the upper equation an amount of thrust is calculated for 50  
134 milligrams of ionized particles traveling at 60% velocity of light in one of the particle  
135 accelerator rings. The particle stream may be brought to a constant velocity, similar to a storage  
136 ring, but with the intent of harnessing upward thrust. For an individual ring, this example  
137 produces  $2.54 \times 10^5$  Newtons of thrust. Although specific values are used for mass, velocity,

138 and thrust, the equations are not limited to these values, nor is it required that the velocity of the  
139 particle stream be constant, in order that upward thrust be developed. Many combinations of  
140 particle stream velocity, and mass are possible, such that varying these configurations while in  
141 flight allows the craft to navigate altitude. Figure 9 is a mathematical model for the purpose of  
142 demonstrating use of equations derived in figure 8. If the vehicle is fitted with two particle  
143 accelerators, with particle flow in counter-rotational directions, it would double the upward  
144 thrust. This should enable 40 metric tons to be lifted upward at an acceleration rate of  $2.9 \text{ m/s}^2$ .  
145 The equation adds upward force, that is generated through gyroscopic lift of the particles, with  
146 downward force of gravity as applied to the deadweight of the ship, to determine the overall  
147 force with which the craft should move. With particle velocity of  $.6c$ , a vehicle , such as a  
148 commercial passenger vehicle, fitted with a circular Particle Accelerator Space Engine around  
149 the perimeter, and deadweight of approximately 40 metric tons would be capable of vertical  
150 acceleration at about  $.3 \text{ g's}$ . In the vacuum of outer space it has the potential to develop a very  
151 high top velocity. Once a desired altitude is found, it may be stabilized by adjusting the particle  
152 stream velocity such that upward thrust that is generated matches the the force of gravity. Any  
153 velocity of circulatory matter exceeding circular orbit velocity may be utilized to harness  
154 upward acceleration and/ or thrust. Thus many combinations of matter quantity, and velocity  
155 may be combined to create and /or navigate using such a propulsion engine.

156 Figures 10 through 12 are a series depicting the methodology for horizontal propulsion,  
157 referred to as "Impulse Propulsion". Figure 10 is a depiction of the centripetal acceleration  
158 pattern for a particle that accelerates during a half cycle, and decelerates during the other half  
159 cycle. Particles, beginning at point A, must increase centripetal acceleration when passing  
160 through each successive point to keep on a circular path, until reaching point F. At point F

161 particles start a decelerative  $\frac{1}{2}$  cycle. Each successive point requires less centripetal acceleration  
162 to maintain the circular path. Equal particle speeds are located at B&J, C&I, D&H, E&G

163         Figure 11 is a depiction of change in acceleration in Cartesian Coordinates. The change  
164 in acceleration is both a change per time, and a change per angle. It must be computed  
165 individually for each point about the circumference of the particle stream. In Cartesian  
166 coordinates, y components cancel, when summed, and a directional component may be found  
167 to cause motion along the x axis. Y components, for change in acceleration, during the  
168 accelerative  $\frac{1}{2}$  cycle, have symmetric, equal but opposite, counterparts in the decelerative  $\frac{1}{2}$   
169 cycle. As such, particles at  $B_y$  provide equal but opposite force along the y axis to particles at  
170  $J_y$ . Particles at  $C_y$  provide equal but opposite force along the y axis to particles at  $I_y$ . Particles  
171 at  $D_y$  provide equal but opposite force along the y axis to particles at  $H_y$ . Particles at  $E_y$   
172 provide equal but opposite force along the y axis to particles at  $G_y$ . This symmetric relation  
173 eliminates recoil acceleration of the ship in the y direction.

174         When the y component of acceleration is eliminated it leaves only the x component of  
175 particle acceleration. As particles are accelerated through stations in one direction, the  
176 accelerator station and ship are accelerated in the opposite direction. During the first  $\frac{1}{2}$  cycle,  
177 particles are accelerated in the negative x direction. The hull of the ship responds by  
178 accelerating in the positive x direction. During the remaining decelerative  $\frac{1}{2}$  cycle, a series of  
179 repulsive forces are placed downstream. Change in particle acceleration is again measured in  
180 the negative x direction. Particles approaching the repulsive force push the ship in the positive x  
181 direction. At points A and F, particles are neither accelerating nor decelerating. The zero net  
182 change in acceleration at those points keeps circular motion but does not add to impulse

183 propulsion. The remaining accelerative and decelerative  $\frac{1}{2}$  cycles have a common direction of  
184 accelerative influence for the space engine in the positive x direction.

185 A symmetry analysis also reveals that if two counter-rotational particle accelerators/  
186 storage rings/ braking device are placed one above another, with low and high velocities found  
187 at common points on the top view circle, then equal velocities should be found at equal points  
188 throughout the both circles. This symmetry aids the mathematical determination of timing  
189 particle kicks on lower and upper accelerator doughnuts. A note need also be made that the  
190 positioning of low point velocity, and high point velocity of the particle stream need not  
191 necessarily be isolated to the intersection of the x axis. Other pairs of points may be utilized  
192 along the perimeter, that have a  $180^0$  relationship to each other, as high and low points of the  $\frac{1}{2}$   
193 cycle relationship. This characteristic allows horizontal propulsion in any direction of the  $360^0$   
194 located in the horizontal plane. In such manner, the Particle Accelerator Space Engine may also  
195 veer left, right or slow down along the plane of the horizon

196 Figure 12 is a depiction of a particle trajectory, for an individual particle, as the vehicle  
197 and Particle Accelerator Space Engine moves through space, and time. Let us say that a circular  
198 accelerator is the means of propulsion for a space craft. From the viewpoint of a passenger, the  
199 particle flow is along a stationary path around them. To a person on the ground the particle path  
200 follows a scribble pattern as the accelerator moves in a forward direction.
